### Lecture 1: Physical Equilibria—The Temperature Dependence of Vapor Pressure

Our first foray into equilibria is to examine phenomena associated with two phases of matter achieving equilibrium in which the free energy in each phase is the same and there is no change in the overall values of system state functions.

The areas of physical equilibria we will investigate are:

- The interface between phases: gas ← → liquids ← → solid. Solution properties like freezing and boiling will be given a thorough thermodynamic treatment.
- Mixtures formed when phases are soluble or miscible in one another. Dissolving solids or gases in liquids or mixing two liquids.
- Colligative properties that derive from mixing of two phases. These are essential properties of biological and chemical systems.

We will draw on the following theoretical treatments from CH 301:

• intermolecular force theory

• thermodynamics

So review these concepts!!

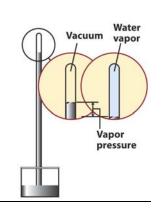

Specifically, review the intermolecular force and thermodynamic lecture notes and worksheets. Pay special attention to the introductory treatment of phases and phase transitions that are presented at various times during these lectures.

#### **Vapor Pressure**

Vapor pressure was introduced in the fall semester as a solution property and we learned that vapor pressure rankings could be qualitatively determined from a ranking of intermolecular forces.

**Definition of vapor pressure**: the pressure exerted by the vapor of a substance that exists in a condensed (liquid or solid) phase.

Just looking at this picture suggests vapor pressure is a surface phenomenon. The more surface the more vapor. The depth of the condensed phase doesn't matter. The reason is that the particles in the condensed phase with the greatest ability to enter the vapor phase are on the surface.

**IMF Theory and vapor phase ranking:** It is intuitive that the stronger the intermolecular force holding a substance together, the less likely it is to enter the vapor phase. Similarly, the smaller the IMF force, the greater the vapor pressure.

Here is the ranking and trend, contrasting IMF and assorted compounds:

As the IMF increases

Instantaneous dipoles (<1 kJ/mole) < dipole-dipole (5 kJ/mole) < H-bonding (20 kJ/mole) < ionic (200 kJ/mole)

The vapor pressure decreases

#### $He > CH_4 > C_3H_8 > CCl_4 > CHCl_3 . CH_3OH > H_2O > NaCl > CaO$

It is pretty easy to generate these qualitative rankings of vapor pressure by first ranking IMF. Look at the table of values for different compounds at  $25^{\circ}$ C to see the correlation:

# **TABLE 8.2** Vapor Pressures at25°C

Substance	Vapor pressure (Torr)	
benzene	94.6	
ethanol	58.9	
mercury	0.0017	
methanol	122.7	
water*	23.8	

\*For values at other temperatures, see Table 8.3.

Now can we create a quantitative measure of vapor pressure?

First recognize that vapor pressure is an equilibrium phenomenon that is temperature dependent.

← note that at equilibrium, as vapor encounters the surface it condenses and the energy released promotes a different particle into the vapor.

 $\leftarrow$  also note that at the higher T more particles achieve separation energy to enter vapor.

	TABLE 8.3 Vap Water	oor Pressure of

	80	355.26
	100	760.00

\*Body temperature.

Can we derive an expression that predicts this relationship? First note that at equilibrium,  $\triangle G_{vap} = G_{gas} - G_{liquid} = 0$ 

 $G_{liquid} = G^{o}$  liquid because it is pressure independent

 $G_{gas} = G^{o}_{gas} + RTlnP$  where RTlnP = correction for change in pressure, so:

 $\triangle \mathbf{G}_{vap} = \mathbf{G}^{o}_{\ gas} + \mathbf{RTlnP} - \mathbf{G}^{o}_{\ liquid} = \mathbf{G}^{o}_{\ gas} - \mathbf{G}^{o}_{\ liquid} + \mathbf{RTlnP}$ 

 $\therefore \triangle G^{\circ}_{vap} = RTlnP$  (the standard free energy of vaporization)

But  $\triangle G^{\circ} \operatorname{vap} = \triangle H^{\circ} \operatorname{vap} - T \triangle S^{\circ} \operatorname{vap}$ So:  $\ln P = - \underline{\triangle G^{\circ}_{\operatorname{vap}}}{RT} = - \underline{\triangle H^{\circ}_{\operatorname{vap}}}{RT} + \underline{\triangle S^{\circ}_{\operatorname{vap}}}{R}$  A constant, assuming ideal gas behavior, because a mole of any kind of gas has about the same entropy. Or multiplying through by e<sup>x</sup>

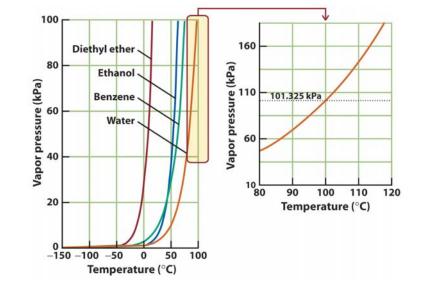

$$\mathbf{P} = \mathbf{K} \mathbf{e}^{-\triangle \mathbf{H} \operatorname{vap/RT}}$$

This is a very famous mathematical relationship that shows up all the time in nature.

What does the above equation suggest for a function? An exponential increase in P with T.

Note this functional relationship not just for water but for other compounds.

Note that as delta H<sup>o</sup><sub>vap</sub> decreases with increasing IMF, the boiling point increases and that this correlates with IMF.

## And now for something really useful that scientists do: Combining equations to eliminate a variable – or how to create the famous Clausius Clapeyron equation.

Given that  $\triangle S^{o}_{vap}$  is assumed to be constant in the expression:

$$\ln P = - \frac{\triangle H^{o}_{vap}}{R} + \frac{\triangle S^{o}_{vap}}{R}$$

We can rearrange the equation to put everything in terms of  $\frac{\Delta Svap^0}{R}$ , identify two states of the system P<sub>1</sub>, T<sub>1</sub> and P<sub>2</sub>, V<sub>2</sub>, set them equal and do mad algebra. When it is all over,

$$\ln \frac{P_2}{P_1} = \frac{\Delta H vap^0}{R} \left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

This is the famous **Clausius-Clapeyron equation** that allows us to use one value of  $P_1$  and  $T_1$  to predict the vapor pressure anywhere else on the graph.

So let's test this by using the equation to find the boiling point of water (hey, at least we'll know if our answer is right since at 100 °C degrees the vapor pressure should be 760 torr). Selecting a P and T from our table of  $H_2O$  vapor pressures. Like 20 °C and 17.54 torr, and given

 $\triangle H^{\circ}_{vap}$  for H<sub>2</sub>O = 40.7 kJ/mole. We need to work in the correct units so convert 17.54 torr into Pa.

1 torr = 133.3 Pa, so 17.54 torr (133.3Pa/1torr) = 2338.1 Pa

rearranging  

$$\ln \frac{P_2}{P_1} = \frac{\Delta H vap^0}{R} \left( \frac{1}{T_1} - \frac{1}{T_2} \right) \qquad \Rightarrow \qquad \qquad \frac{1}{T_1} = \frac{1}{T_2} + \frac{R}{\Delta H vap^0} \ln \frac{P_2}{P_1}$$

And substituting with 1 atm = 101,325 Pa

$$\frac{1}{T_1} = \frac{1}{(20+273)} + \left(\frac{8.3145 \, J/kmole}{40,700 \, J/mole}\right) \ln \left(\frac{2338.1Pa}{101,325Pa}\right)$$

Answer:  $T_1 = 378$ K or  $105^{\circ}$ C

Of course the answer should be 100 °C but the answer get get is pretty good considering all the approximations.

So there we have it, an equation that models the vapor pressure curve for any compound as a function of temperature!!!
